

APPARATUS AND METHOD FOR MELT SPINNING A SYNTHETIC YARN

Cross Reference to Related Application

The present application is a continuation of copending international application Serial No.

5 PCT/EP99/05203, filed 21 July 1999 and designating the USA.

Background of the Invention

10 The invention relates to an apparatus and method for melt spinning a synthetic yarn.

EP 0 682 720 and corresponding U.S. Patent No. 5,976,431 disclose a melt spinning apparatus and method wherein freshly extruded filaments are advanced in a cooling tube with a vacuum atmosphere. The cooling tube 15 is arranged at a distance from the spinneret, so that an air stream develops in the cooling tube for cooling the filaments in the direction of the advancing yarn. In this connection, the flow velocity of the air and the spinning speed are adapted to each other such that the 20 air stream assists the filaments in their advance in the cooling tube. With that, it is accomplished that the solidification point of the filaments moves away from the spinneret. This leads to a delayed crystallization of the polymer that favorably influences the physical 25 properties of the yarn. Thus, for example, in the production of POY yarn, it was possible to increase the withdrawal speed and, thus, the draw ratio, without changing the elongation values necessary for further processing of the yarn.

30 The known spinning apparatus consists of a cooling tube and a suction device downstream of the spinneret. Between the spinneret and the cooling tube, an inlet cylinder extends with a gas permeable wall. By the

0927452-012301

interaction of the inlet cylinder and the suction device, a quantity of air is introduced within the spin shaft and guided within the cooling tube as an accelerated air stream in the direction of the advancing yarn. As the 5 filaments pass through the inlet cylinder, they are precooled in such a manner that an increase of viscosity in the surface layers causes the firmness of the surface layer to increase. Upon their entry into the cooling tube, the filaments are still molten in their core, so 10 that final solidification occurs only in the cooling tube. To this end, the cooling tube consists of a funnel-shaped inlet with a narrowest cross section in the cooling tube and cylindrical portion directly adjacent thereto. The narrowest cross section and the cylindrical 15 portion cause the air stream to accelerate such that the filaments are assisted in their advance and undergo a delayed solidification only in the cooling tube. However, in the case of coarser filament deniers, the problem arises that while the air stream entering the 20 cooling tube assists the advance of the filaments, it will not lead to an adequate cooling of the filaments. Although the known spinning apparatus is provided with an air supply device at the inlet end of the cooling tube for generating an additional cooling stream, same leads, 25 however, to a considerable cooling of the filaments already before the air stream is accelerated in the cooling tube, so that the positive effect of a delayed crystallization of the polymer is not effective or only inadequately effective.

30 It is therefore an object of the invention to improve the initially described spinning apparatus and method such that filaments with coarser deniers are adequately cooled over a short distance, even in the case

102001.012301.35479760

of delayed crystallization of the polymer, and at high spinning speeds.

### Summary of the Invention

5 The above and other objects and advantages of the  
invention are achieved by the provision of a melt  
spinning apparatus and method which includes an extruder  
for heating a polymeric material and extruding the  
resulting melt through a spinneret nozzle to form a  
10 plurality of downwardly advancing filaments. A cooling  
tube is disposed below the spinneret nozzle and comprises  
an inlet, a cylindrical portion below the inlet, and an  
outlet. A gas permeable inlet cylinder is positioned  
between the spinneret nozzle and the inlet of the cooling  
15 tube, and a suction generating device is connected to the  
outlet of the cooling tube so as to generate an initial  
cooling air stream through the cooling tube in the  
direction of the advancing filaments. An air supply  
device is provided for generating an additional cooling  
20 air stream in the cooling tube, with the air supply  
device being positioned downstream of the inlet of the  
cooling tube. Also, guide means is provided for  
gathering the advancing filaments to form an advancing  
multifilament yarn, and a winder serves to wind the  
25 advancing multifilament yarn into a package.

The invention has the advantage that the initial air stream present at the inlet end of the cooling tube serves to delay exclusively crystallization of the polymer. This ensures that the solidification point of the filaments is inside the cooling tube. For further cooling of the filaments, use is made of the additional cooling air stream that is introduced by the air supply device. To this end, this air supply device is arranged downstream of the narrowest cross section of the inlet in

the cylindrical portion or downstream of the outlet end of the cooling tube. With that, it is accomplished that the additional cooling air stream contacts the filament bundle only shortly before or after solidification of the filaments. This influences in particular the evenness of the filament cross sections and results in a high spinning reliability and absence of lint.

5 In one preferred embodiment, the air supply device connects to the cooling tube so that the additional cooling air stream and the initial cooling air stream flow together in the direction of the advancing filaments. Since the two air streams are equidirectional, turbulence is essentially avoided.

10 15 In this connection, it is possible to construct the air supply device in a simple manner by an opening in the wall of the cooling tube. The cooling stream entering the cooling tube through the opening adjusts itself automatically due to the vacuum atmosphere in the cooling tube.

20 25 A further development of the invention provides that the air stream entering at the inlet end of the cooling tube and the additional cooling air stream entering the cooling tube through the opening are adjustable independently of each other. To this end, the air supply device comprises an air stream generator that generates the additional cooling air stream. The air stream generator could be, for example, a blower.

30 In a particularly advantageous embodiment of the spinning apparatus, the air stream generator is constructed as an injector with a nozzle bore that connects to a source of compressed air. In this arrangement, the nozzle bore of the injector terminates directly in the opening in the wall of the cooling tube. Also, the center axis of the cooling tube and the nozzle

100-25623760

bore form an acute angle in direction of the advancing yarn, so as to introduce into the cooling tube the additional cooling air stream so as to have a directional component in direction of the advancing yarn. Such a 5 configuration of the spinning apparatus is also suitable in particular for threading the filaments into the cooling tube at the start of the process. An angle range from 15°C to 30°C further provides that in the region of the cooling air stream the filament bundle is safely kept 10 off the wall of the cooling tube.

To adjust the cooling air stream as a function of the filament type and filament denier, the free flow cross section of the opening may be adjustable by means of a sleeve mounted on the cooling tube, and which is 15 arranged for movement along the cooling tube for closing the opening in full or in part.

In an advantageous further development, the adjustment device may comprise an air chamber enclosing the opening in the cooling tube on the outside. This air 20 chamber has a supply line with a throttling device. Thus, it is possible to control the air supply to the air chamber by means of the throttling device in the supply line.

To achieve with the cooling stream a most intensive 25 possible cooling, it is possible to connect the supply line of the air chamber to the air stream generator.

In the above embodiments, the opening arranged in the wall of the cooling tube may be made as a bore or a radial cutout. In a particularly advantageous further 30 development of the spinning apparatus, the opening is formed by an annular, perforated sheet element in the wall of the cooling tube. In this instance, the perforated sheet element extends about the entire circumference of the cooling tube. This ensures a

09762452.012204

uniform inflow of the cooling air stream into the cooling tube. The plurality of holes permits a flow to be generated that has little turbulence.

The perforated sheet element may be made conical  
5 with a cross section increasing in direction of the  
advancing yarn and arranged in the extension of the  
cooling tube at the outlet end thereof. With that,  
cooling of the filaments is further intensified since the  
expansion of the air stream effects a better mixing  
10 between the initial cooling air stream and the additional  
air stream.

Besides a very intensive cooling, a particularly advantageous further development facilitates a preliminary drawing of the filaments. Here, the additional cooling air stream is oppositely directed to the direction of the advancing yarn and generates on the filaments a frictional force that acts against the direction of the advancing yarn. This frictional force effects a drawing of the filaments.

20 In another embodiment, the air supply device is constructed such that the suction device can generate the additional cooling air stream. To this end, a second cooling tube connects as an extension to the first cooling tube directly to the outlet chamber of the  
25 suction device.

To equalize the flow, it is preferred to construct the second cooling tube with a funnel-shaped inlet and a cylindrical outlet with an air-permeable wall.

To increase the draw effect in the case of such an air supply device, the cooling tube could include a heating device.

The method of the present invention is characterized in particular in that it permits production of textile or industrial yarns of polyester, polyamide, or

polypropylene with coarse deniers and high elongation values. The method may be coupled with different treatment devices, so that, for example, fully drawn yarns, partially oriented yarns, or highly oriented yarn can be produced.

Brief Description of the Drawings

In the following, several embodiments of the melt spinning apparatus according to the invention are described in more detail with reference to the accompanying schematic drawings, in which:

Figure 1 illustrates a first embodiment of a spinning apparatus according to the invention with a takeup device downstream thereof;

Figure 2 illustrates a further embodiment of a spinning apparatus according to the invention with an air supply device arranged on the cooling tube;

Figure 3 illustrates a further embodiment of an air supply device; and

Figures 4 and 5 illustrate further embodiments of the spinning apparatus according to the invention with an air supply device.

Detailed Description of the Preferred Embodiments

Figure 1 shows a first embodiment of an apparatus for spinning a synthetic yarn according to the invention. As illustrated, a yarn **12** is spun from a heated thermoplastic material. To this end, an extruder or a pump melts the thermoplastic material, and a spin pump delivers the melt via a melt line **3** to a heated spin head **1**. The underside of spin head **1** mounts a spinneret nozzle **2**. From the spinneret nozzle **2**, the melt emerges in the form of fine filament strands **5**, which advance as a filament bundle through a spin shaft **6** that includes an

09767452.012301

inlet cylinder **4** which is formed by a perforated wall **7**. To this end, the inlet cylinder **4** is positioned directly downstream of spin head **1** and surrounds the filaments **5**.

In the direction of the advancing yarn, a cooling tube **8** connects to the bottom free end of inlet cylinder **4**. At the inlet end, the cooling tube **8** comprises an inlet **9**, which is preferably funnel-shaped and connects to the inlet cylinder **4**. In the narrowest cross section of inlet **9**, the cooling tube **8** comprises a second, cylindrical portion **32**. At the end of cylindrical portion **32**, the cooling tube **8** comprises an outlet cone **10** that forms an outlet **33**. The outlet cone **10** terminates in an outlet chamber **11**. On its underside, the outlet chamber **11** mounts an air supply device **34**, which includes a second cooling tube **35**. From the underside of outlet chamber **11**, the second cooling tube **35** extends coaxial with the first cooling tube **8**. At its inlet end, the second cooling tube **35** comprises a funnel-shaped inlet **36** that connects to the outlet chamber **11**. The free end of the second cooling tube **35** forms a cylindrical outlet **37** which has a gas permeable wall. The outlet comprises at its bottom end an outlet opening **13**, from which the filaments **5** emerge.

A suction line **14** terminates in suction chamber **11** on one side thereof. Via suction line **14**, a suction device **15** arranged at the free end of suction line **14** connects to outlet chamber **11**. The suction device **15** may comprise, for example, a vacuum pump or a blower that generates a vacuum in outlet chamber **11** and, thus, in the first cooling tube **8** and in the second cooling tube **35**. Between the outlet **33** of the first cooling tube and the inlet **36** of the second cooling tube **35**, the outlet chamber **11** accommodates a screen cylinder **30** that

7020707.25672027600  
4

surrounds the filaments 5. The screen cylinder 30 has an air permeable wall.

In the plane of the advancing yarn downstream of the air supply device 34, a lubrication device 16 and a 5 takeup device 20 are arranged. The takeup device 20 includes a yarn guide 19. The yarn guide 19 indicates the start of a traversing triangle that results from the reciprocal movement of a traversing yarn guide of a yarn traversing device 21. Downstream of the yarn traversing 10 device 21, a contact roll 22 is arranged. The contact roll 22 lies against the circumference of a package 23 that is to be wound. The package 23 is wound on a rotating winding spindle 24. To this end, a spindle motor 25 drives the winding spindle 24. The drive of the 15 winding spindle 25 is controlled as a function of the rotational speed of the contact roll such that the circumferential speed of the package and, thus, the winding speed remain substantially constant during the winding operation.

20 Between the lubrication device 16 and the takeup device 20, a treatment device 17 is arranged for treating the yarn 12. In the embodiment shown in Figure 1, an entanglement nozzle 18 forms the treatment device 17.

25 As a function of the production process, it is possible to arrange in the treatment device one or more heated or unheated godets, so that the yarn is drawn before being wound. There is likewise a possibility of arranging additional heating devices for drawing or relaxing within the treatment zone 17.

30 In the spinning apparatus shown in Figure 1, a polymer melt is delivered to the spin head 1 and extruded through spinneret nozzle 2 to form a plurality of downwardly advancing filaments 5. The filament bundle is withdrawn by the takeup device 20. In this process, the

1002370-25h29760

filament bundle advances at an increasing speed through spin shaft 6 within inlet cylinder 4. Subsequently, the filament bundle enters cooling tube 8 through the funnel-shaped inlet 9. In the cooling tube 8, suction device 15 generates a vacuum. Ambient air outside of inlet cylinder 4 is thereby sucked into spin shaft 6. The air entering spin shaft 6 is proportional to the gas permeability of the wall 7 of inlet cylinder 4. The inflowing air leads to a precooling of the filaments, so that their surface layers firm up. In their core, however, the filaments remain molten. The quantity of air is then sucked together with the filament bundle through inlet 9 into cooling tube 8. The air stream is accelerated due to the narrowest cross section formed at the end of inlet 9 and the action of suction device 15 such that an air stream counteracting the movement of the filaments is no longer present in the cooling tube. The narrowest cross section extends over the entire region of cylindrical tube portion 32. Thus, the length of cylindrical tube portion 32 defines the acceleration distance within cooling tube 8. In this connection, the cylindrical tube portion may have a length from few millimeters to 500 mm or greater. The air stream in the direction of the advancing yarn decreases the stress on the filaments, and the solidification point moves away from the spinneret. It is thus possible to influence the relationship between spinning speed and drawing during the production of the yarn such that high elongation values are obtained despite high spinning speeds. Within the cooling tube 8, the filaments undergo a cooling.

For a further cooling, the air supply device generates an additional cooling air stream. To this end, the filaments advance through the second cooling tube 35 downstream of first cooling tube 8. The outlet cone 10

050210 25120760

of the first cooling tube and the funnel-shaped inlet **36** of the second cooling tube **35** both terminate in the outlet chamber **11**. The air stream from cooling tube **8** and the additional cooling air stream from cooling tube **35** are sucked under the action of suction device **15** into the outlet chamber **11**. They exit therefrom via screen cylinder **30** through suction line **14**. Thereafter, the entire air stream is removed by suction device **15**.

On the outlet side of cooling tube **35**, the filaments **5** emerge from outlet opening **13**, and enter the lubrication device **16**, which combines the filaments to a yarn **12**. To increase cohesion, the yarn **12** is entangled in an entanglement nozzle **18** before being wound. In the takeup device, the yarn **12** is wound to a package **23**.

It is possible to use the arrangement shown in Figure 1 to produce, for example, a polyester yarn that is wound at a takeup speed greater than 7,000 m/min. The spinning apparatus of Figure 1 is characterized in that the air quantity entering the inlet cylinder is adapted to the delayed heat treatment of the filaments. In this connection, it is possible to influence with advantage both precooling and delayed solidification of the filaments. The final cooling of the filaments occurs in a second zone that is formed by the second cooling tube **35**. To intensify the cooling, it would be possible to supplement air supply device **35** with an air stream generator that could connect to the outlet end of the second cooling tube **35**.

Figure 2 shows a further embodiment of a spinning apparatus according to the invention, wherein an air supply device **34** with an air stream generator **38** is provided.

The spinning apparatus shown in Figure 2 differs from the embodiment shown in Figure 1 by the

DOCKET NUMBER  
01230-257250

configuration of the air supply device 34. Therefore, as regards the description of the remaining structural elements that are indicated by identical numerals, the description of the embodiment of Figure 1 is herewith incorporated by reference.

In the embodiment of the spinning apparatus as shown in Figure 2, the air supply device **34** is arranged in the region of the cylindrical portion **32** of the cooling tube **8**. To this end, the cooling tube **8** comprises an opening **39** in the wall of cylindrical tube portion **32**. The opening **39** is formed by an annular, perforated sheet element **40** that is inserted into the wall of cylindrical tube portion **32**. The opening **39** in the wall of cylindrical tube portion **32** is enclosed by an air chamber **42** externally surrounding the wall of cylindrical tube portion **32**. The air chamber **42** is connected to a supply line **41**, which in turn connects to an air stream generator **38**. Between air stream generator **38** and air chamber **42**, the supply line **41** accommodates an adjustable throttle **44**, which is adapted for controlling the free flow cross section of supply line **41**.

In the embodiment of the spinning apparatus according to the invention as shown in Figure 2, the additional air stream is generated by the interaction of suction device 15 and air stream generator 38 of air supply device 34. In this arrangement, the additional cooling air stream enters the acceleration length of cooling tube 8 through opening 39. To avoid turbulence inside the cooling tube 8, the cooling air stream enters opening 39 through a plurality of perforations of the perforated sheet element 40. The additional cooling air stream and the initial air stream mix and flow in the direction of the advancing yarn to the outlet 33 of cooling tube 8. There, the additional cooling air stream

and the air stream enter outlet chamber 11, and are removed by suction device 15 via suction line 14. The filament bundle is cooled inside cooling tube 8. On the underside of outlet chamber 11, the filament bundle 5 leaves the cooling zone through the outlet opening 13. Subsequently, a lubrication device 16 combines the filament bundle to the yarn.

The embodiment shown in Figure 2 is characterized in that an intense cooling can occur within the cooling tube 10 despite a delayed cooling and, thus, the relocation of the solidification point.

The air stream entering at inlet 9 of cooling tube 8 and the position of the air supply device 34 on the cooling tube are adapted such that the additional cooling 15 air stream enters the cooling tube 8 shortly before or shortly after the solidification point of the filaments. Thus, a relatively great uniformity is accomplished in the formation of the filaments or yarn.

An opening that is locally defined on the 20 circumference may also form the air supply device 34. Likewise, it is possible to construct the air supply device 34 without air stream generator 38, so that ambient air is able to enter directly the air chamber 42, via supply line 41, due to the action of suction device 25 15.

Figure 3 shows a modification of the air supply device 34, as could be used, for example, in the spinning apparatus of Figure 2. In this embodiment, an axially slidable sleeve 43 covers the openings 39 in the 30 perforated sheet element 40. The portion of openings 39 that are not covered by sleeve 43 connects to the ambient air. Thus, due to the vacuum atmosphere in cooling tube 8, an additional cooling air stream will form that flows via the free flow cross section of openings 39 into the

100000-25429260

interior of cooling tube 8. In direction of the advancing yarn upstream of air supply device 34, the filaments 5 are contacted by the air stream sucked in at the inlet end of air supply device 34, which delays 5 cooling of the filaments. Only after the filaments 5 have passed air supply device 34, will cooling of the filaments be intensified by the additionally inflowing cooling air stream, so that the filaments are cooled when they leave cooling tube 8. By adjusting the sleeve 43, 10 it is possible to regulate the air quantity for forming the cooling air stream as a function of the yarn denier or polymer type.

Figure 4 shows a further embodiment of an air supply device 34. The spinning apparatus is identical with the embodiment of Figure 2. To this extent, the description of Figure 2 is herewith incorporated by reference.

In the embodiment of the spinning apparatus of Figure 4, the air supply device 34 is formed at the outlet end of cooling tube 8. To this end, the outlet cone 10 comprises a gas-permeable wall. The openings 39 in the wall of cooling tube 8 thus extend from the end of cylindrical tube portion 32 to the outlet 33. The gas-permeable wall of outlet cone 10 is arranged inside an air chamber 42 that surrounds cooling tube 8. The air chamber 42 comprises a supply line 41 that connects at its end to the ambient air. An adjustable throttle 44 controls the free flow cross section of supply line 41.

In the spinning apparatus shown in Figure 4, suction device 15 generates the additional cooling air stream. 30 In this process, the ambient air enters air chamber 42 through supply line 41. From the air chamber 42, the ambient air enters the cooling tube due to the vacuum atmosphere therein through the air-permeable wall of outlet cone 10. Based on the widening cross section in

direction of the advancing yarn, an intense mixing occurs between the air stream accompanying the filaments and the laterally entering cooling air stream. This results in an intense cooling of the filaments. The cooling air stream and air stream are removed by suction device 15 through outlet chamber 11 and suction line 14.

Figure 5 shows a further embodiment of a cooling system of a spinning apparatus. In this embodiment, the air supply device is arranged downstream of inlet 9 in the region of the cylindrical portion 32 of cooling tube 8. To this extent, the embodiment shown in Figure 5 is identical with the embodiment shown in Figure 2, whose description is herewith incorporated by reference.

The air supply device 34 of Figure 5 comprises an opening 39 in the wall of cooling tube 8 that is constructed in the form of a bore. Furthermore, the air supply device comprises an injector 45 and a source of compressed air 47. The source of compressed air 47 connects to a nozzle bore 46 of injector 45. The injector 45 and the source of compressed air 47 act as an air stream generator and advance a cooling air stream through the opening 39 into the interior of cooling tube 8. The nozzle bore 46 of injector 45 is made such that between the center axis of the cooling tube and the nozzle bore an angle < 90° forms in the direction of the advancing yarn. Thus, the cooling air stream is directed in the direction of the advancing yarn into the interior of cooling tube 8.

Besides the cooling effect, the embodiment of the air supply device of Figure 5 has proven itself in particular for threading the filaments at the beginning of the process. The injector introduces the additional cooling air stream at a high acceleration into the interior of the cooling tube. Due to the suction effect

40627025450

of suction device 15, this cooling air stream propagates substantially in the center region of the tube cross section. This flow entrains the filaments and guides the filament bundle reliably through cooling tube 8. To 5 further increase the effect, it would be possible to arrange on the opposite side of the wall a second or further air supply device with injector.

The air supply devices shown in Figures 2-4 comprise each annular openings that extend over the entire 10 circumference of the cooling tube. However, it is also possible to limit the openings to extend only partially over a certain circumferential section of the cooling tube. It is also possible to form several openings side by side and/or one after the other in the wall of the 15 cooling tube. The configuration of the openings or insertion of porous walls, such as for example the perforated sheet element, permit the flow of the cooling air stream to enter the interior of the cooling tube substantially without causing major turbulences. The 20 embodiment of the air supply device shown in Figure 4 generates a flow with especially little turbulence for cooling the filaments, which increases spinning reliability or the stabilized advance of the yarn.

The invention is not limited to a certain 25 configuration of the cooling tube. The cylindrical shapes illustrated in the embodiments are exemplary and may easily be replaced with an oval shape, or even with an angular shape of the cooling tube when rectangular spinnerets are used.

30 It can as well be advantageous, especially for the production of highly oriented yarns, to make the cylindrical portion of the cooling tube very short. In an extreme case the cooling tube could consist of an inlet cone and an outlet cone only, such that the air

03737452.042301

supply device according to the embodiment as shown in Fig. 2 would be located in the region of the outlet cone 10.

Many modifications and other embodiments of the 5 invention will come to mind to one skilled in the art to which this invention pertains having the benefit of the teachings presented in the foregoing descriptions and the associated drawings. Therefore, it is to be understood that the invention is not to be limited to the specific 10 embodiments disclosed and that modifications and other embodiments are intended to be included within the scope of the appended claims. Although specific terms are employed herein, they are used in a generic and descriptive sense only and not for purposes of 15 limitation.

09767452 - 032301
